Domain Decomposition Methods for Partial Differential Equations

David E. Keyes

Department of Applied Physics & Applied Mathematics Columbia University

Opening inspiration

"... at this very moment the search is on – every numerical analyst has a favorite preconditioner, and you have a perfect chance to find a better one."

- Gil Strang (1986)

Definition and motivation

- Domain decomposition (DD) is a "divide and conquer" technique for arriving at the solution of problem defined over a domain from the solution of related problems posed on subdomains
- *Motivating assumption #1:* the solution of the subproblems is qualitatively or quantitatively "easier" than the original
- *Motivating assumption #2:* the original problem does not fit into the available memory space
- *Motivating assumption #3 (parallel context):* the subproblems can be solved with some concurrency

Remarks on definition

- "Divide and conquer" is not a fully satisfactory description
 - "divide, conquer, and *combine*" is better
 - combination is often through iterative means
- True "divide-and-conquer" (only) algorithms are rare in computing (unfortunately)
- It might be preferable to focus on "subdomain composition" rather than "domain decomposition"

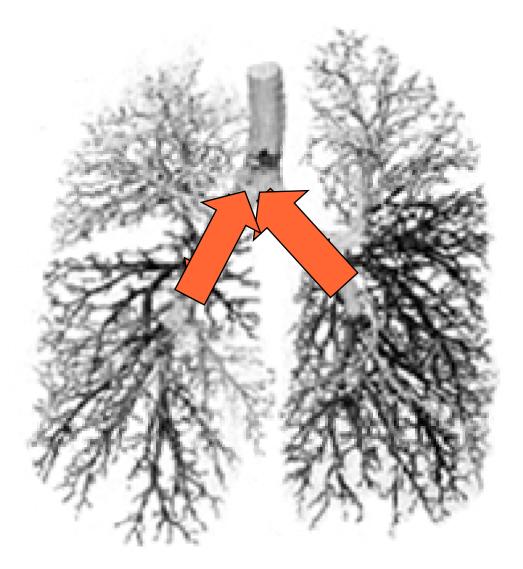

We often think we know all about "two" because two is "one and one". We forget that we have to make a study of "and."

A. S. Eddington (1882-1944)

Remarks on definition

- Domain decomposition has generic and specific senses within the universe of parallel algorithms
 - generic sense: any data decomposition (considered in contrast to task decomposition)
 - specific sense: the domain is the domain of definition of an operator equation (differential, integral, algebraic)
- In a generic sense the process of constructing a parallel program consists of
 - Decomposition into tasks
 - Assignment of tasks to processes
 - Orchestration of processes
 - Communication and synchronization
 - Mapping of processes to processors

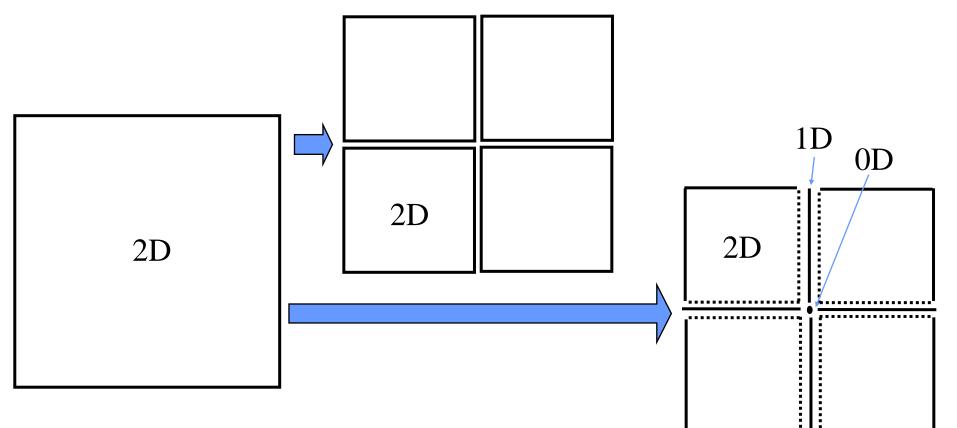

Divide, conquer, and combine – as natural as breathing

- Most of the *volume* of the lung just transports air and blood down ("divide" phase) to microstructures, where they mix
- Most of the *area* of the lung is at these smallest scales, where gaseous exchange ("conquer") occurs efficiently
- The oxygenated blood and deoxygenated air then "recombine" for output

Subproblem structure

• The subdomains may be of the same or different dimensionality as the original

Plan of presentation

- Imperative of domain decomposition (DD) for terascale computing (and beyond)
- Basic DD algorithmic concepts
 - Schwarz
 - Schur
 - Schwarz-Schur combinations
- Basic DD convergence and scaling properties
- En route:
 - mention some "high watermarks" for DD-based simulations

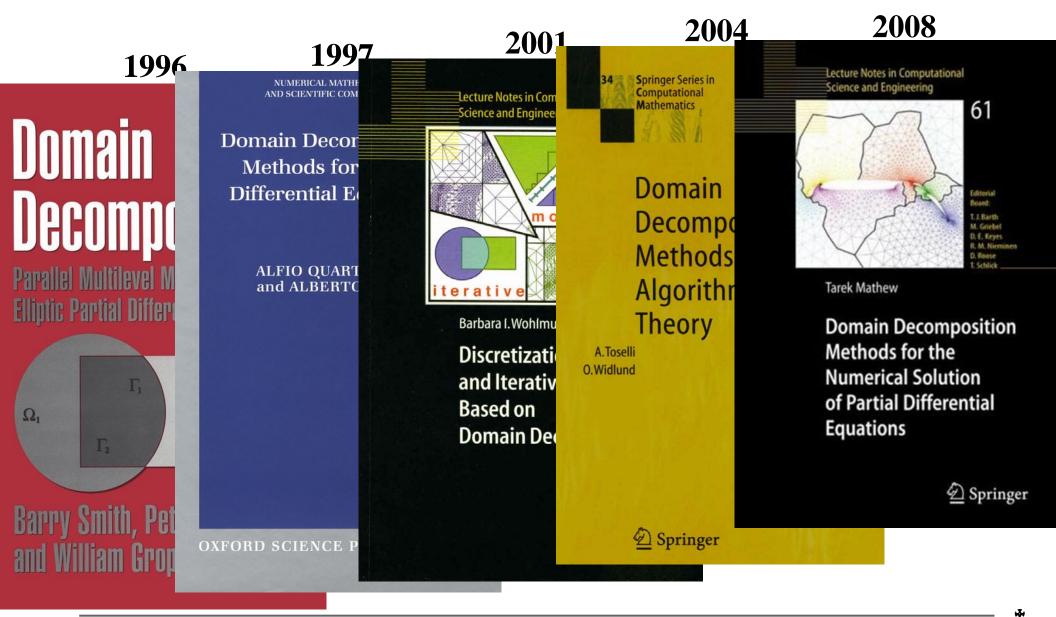

Caveat

- This talk is *Part I* of a three-hour short course sometimes done "tag-team" with Olof Widlund, NYU
- Part II contains material on the very successful class of discontinuous domain decomposition methods known as mortar and "FETI" (finite element tearing and interconnection), not covered in today's talk (though invented here in Boulder ^(C))
- Also not covered here are recent interesting developments in optimized Schwarz methods
- The speakers *likes* these methods and believes they are important in practice; their omission is purely a matter of scope
- *However*, software for them is not as readily available as the software to be discussed in connection with Schwarz methods here

Prime sources for domain decomposition

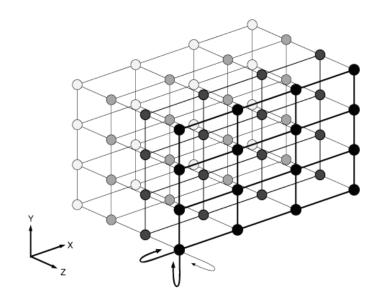

+ DDM.ORG and other proceedings volumes, 1988-2008

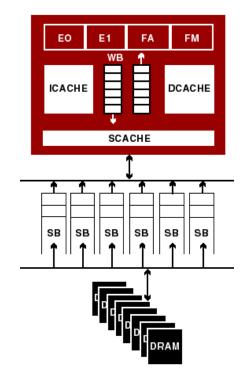

Algorithmic requirements from architecture

• Must run on physically distributed memory units connected by message-passing network, each serving one or more processors with multiple levels of cache

"horizontal" aspects

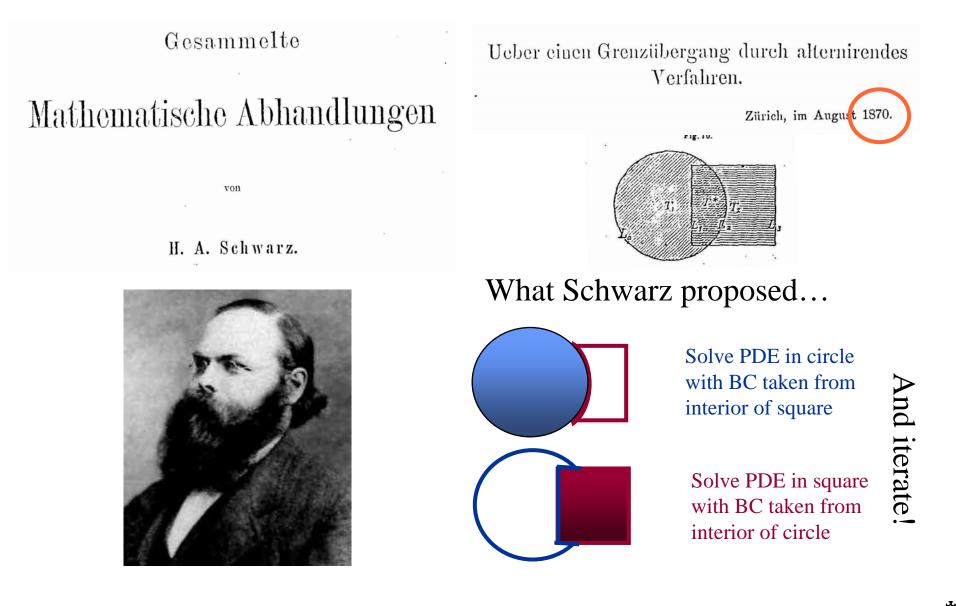

Building platforms is the "easy" part

• Algorithms must be

- highly concurrent and straightforward to load balance
- latency tolerant
- cache friendly (good temporal and spatial locality)
- highly scalable (in the sense of convergence)
- Domain decomposition "natural" for all of these
- Domain decomposition also "natural" for software engineering
- Fortunate that its theory was built in advance of requirements!

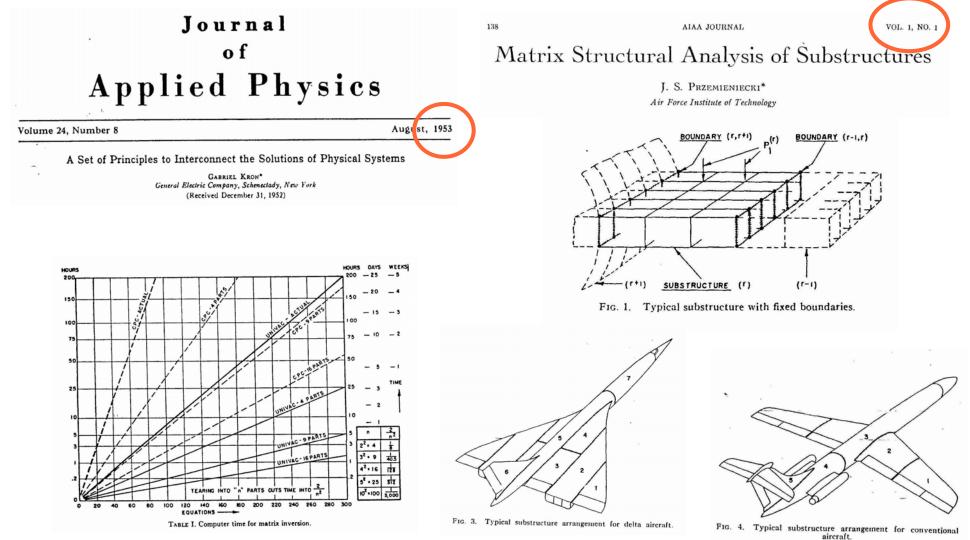

The earliest DD paper?

Rationale

- Convenient analytic means (separation of variables) are available for the regular problems in the subdomains, but not for the irregular "keyhole" problem defined by their union
- Schwarz iteration defines a functional map from the values defined along (either) artificial interior boundary segment completing a subdomain (arc or segments) to an updated set of values
- A *contraction map* is derived for the error
- Rate of convergence is not necessarily rapid this was not a concern of Schwarz
- Subproblems are not solved concurrently neither was this Schwarz' concern

Other early DD papers

Rationale

- *For Kron:* direct Gaussian elimination has superlinear complexity
 - union of subproblems and the connecting problem (each also superlinear) could be solved in fewer overall operations than one large problem
- For Przemieniecki: full airplane structural analysis would not fit in memory of available computers
 - individual subproblems fit in memory

Rationale

- Let problem size be *N*, number of subdomains be *P*, and memory capacity be *M*
- Let problem solution complexity be N^a , $(a \ge 1)$
- Then subproblem solution complexity is $(N/P)^a$
- Let the cost of connecting the subproblems be c(N, P)
- Kron wins if $P(N/P)^a + c(N,P) < N^a$

or $c(N,P) < N^a (1-P^{1-a})$

NB: Kron does not win directly if *a*=1 !

• Przemieniecki wins if

Przemieniecki's prediction (1963)

"From past experiences with the analysis of aircraft structures, it is evident that some form of structural partitioning is usually necessary, either because different methods of analysis are used on different structural components or because of the limitations imposed by digital computers. *Even when the next generation of faster and larger digital computers becomes a well-established tool for the analysis of aircraft structures*, it seems rather doubtful, because of the large number of unknowns, that the substructure displacement method of analysis would be wholly superseded by an overall analysis carried out on the complete structure."

Contemporary interest

• Goal is algorithmic scalability:

fill up memory of arbitrarily large machines to increase resolution, *while preserving nearly constant** *running times* with respect to proportionally smaller problem on one processor

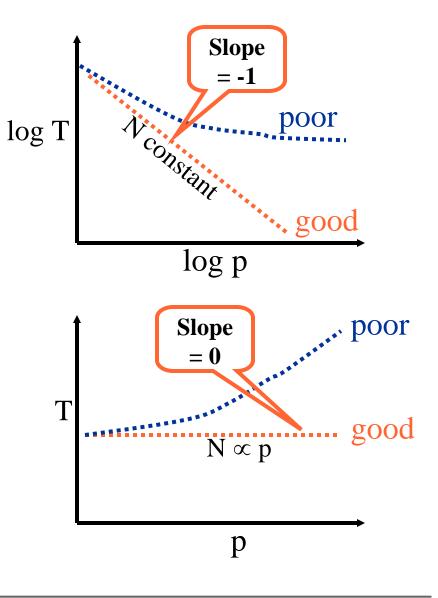

Two definitions of scalability

- "Strong scaling"
 - execution time decreases in inverse proportion to the number of processors
 - fixed size problem overall

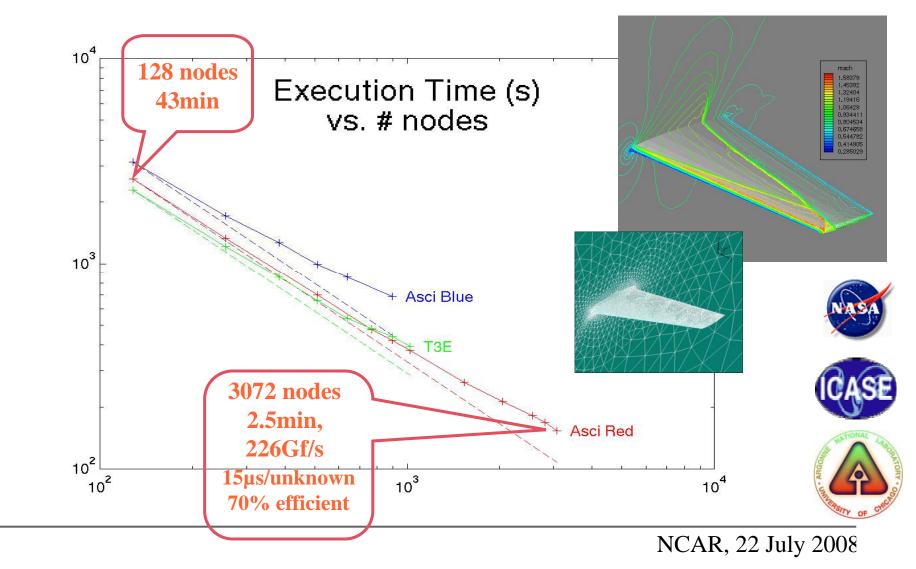

"Weak scaling"

- execution time remains constant, as problem size and processor number are increased in proportion
- fixed size problem per processor
- also known as "Gustafson scaling"

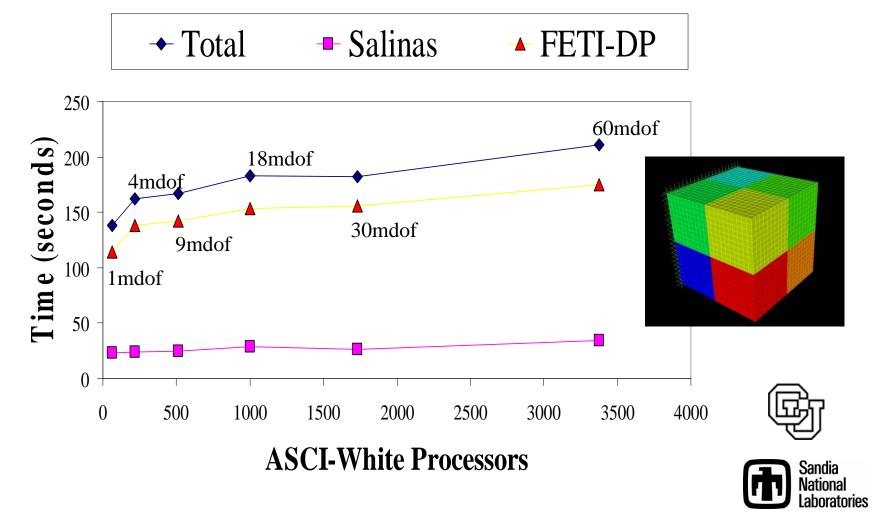

Strong scaling illus. (1999 Bell Prize)

- Newton-Krylov-Schwarz (NKS) algorithm for compressible and incompressible Euler and Navier-Stokes flows
- Used in NASA application FUN3D (M6 wing results below with 11M dof)

Weak scaling illus. (2002 Bell Prize)

- Finite Element Tearing and Interconnection (FETI) algorithm for solid/shell models
- Used in Sandia applications Salinas, Adagio, Andante

Decomposition strategies for $\mathcal{L}u=f$ **in** Ω

• Operator decomposition

$$\mathcal{L} = \sum_{k} \mathcal{L}_{k}$$

• Function space decomposition

$$f = \sum_{k} f_k \Phi_k, u = \sum_{k} u_k \Phi_k$$

• Domain decomposition

$$\Omega = \bigcup_{k} \Omega_{k}$$

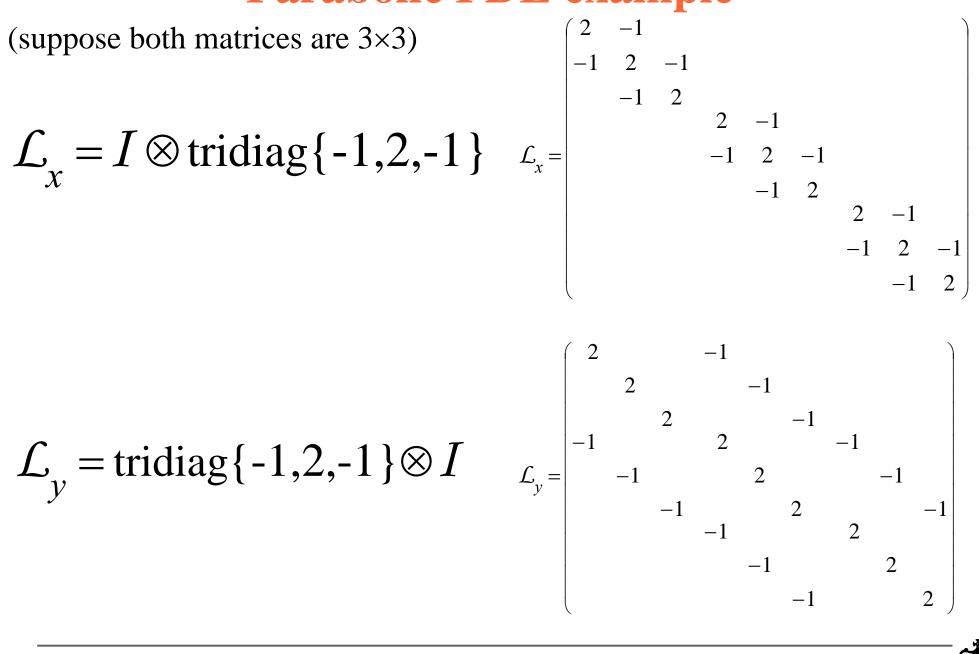

Parabolic PDE example

• Continuous

 $\begin{aligned} & \left(\frac{\partial}{\partial t} - \nabla^2\right) u = f \\ & \left(\frac{I}{\partial t} - \nabla^2\right) u^{(k+1)} = \frac{I}{-u} u^{(k)} + f \end{aligned}$ • Semi-discrete in time • Spatial discretization

$$\begin{bmatrix} \frac{I}{\tau} + \frac{1}{h^2} (\mathcal{L}_x + \mathcal{L}_y) \end{bmatrix} u^{(k+1)} = \frac{I}{\tau} u^{(k)} + f$$
$$\mathcal{L}_x = I \otimes \operatorname{tridiag} \{-1, 2, -1\}$$
$$\mathcal{L}_y = \operatorname{tridiag} \{-1, 2, -1\} \otimes I$$

Parabolic PDE example

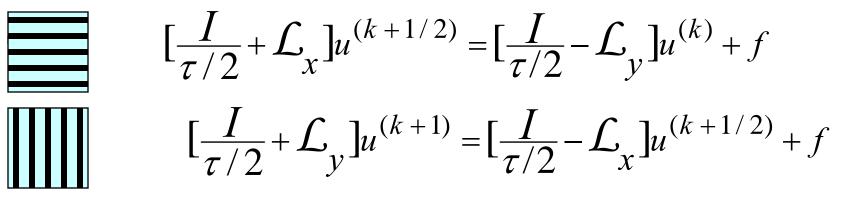

Parabolic PDE example

Operator decomposition

• Consider ADI

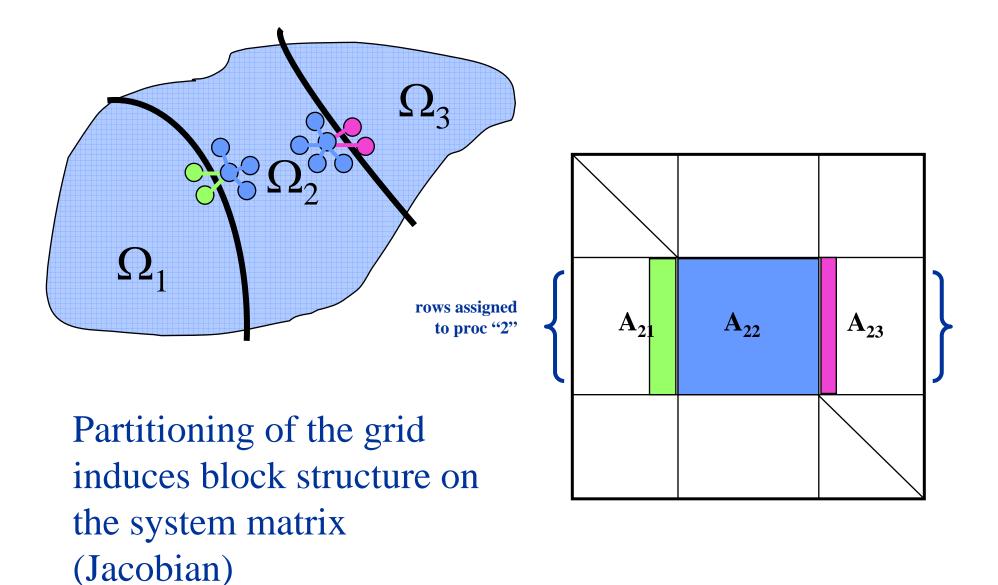

- Iteration matrix consists of four multiplicative substeps per timestep
 - two sparse matrix-vector multiplies
 - two sets of unidirectional bandsolves
- Parallelism *within* each substep
- But global data exchanges *between* bandsolve substeps

Function space decomposition

- Consider a spectral Galerkin method $u(x, y, t) = \sum_{j=1}^{N} a_j(t) \Phi_j(x, y)$ $\frac{d}{dt}(\Phi_i, u) = (\Phi_i, \mathcal{L}u) + (\Phi_i, f), i = 1, ..., N$ $\sum_j (\Phi_i, \Phi_j) \frac{da_j}{dt} = \sum_j (\Phi_i, \mathcal{L}\Phi_j) a_j + (\Phi_i, f), i = 1, ..., N$ $\frac{da_j}{dt} = M^{-1} K a + M^{-1} f$
- Method-of-lines system of ODEs
- **Perhaps** $M \equiv [(\Phi_j, \Phi_i)], K \equiv [(\Phi_j, \mathcal{L}\Phi_i)]$ are diagonal matrices
- Parallelism across spectral index
- But global data exchanges to *transform back* to physical variables at each step

SPMD parallelism w/domain decomposition

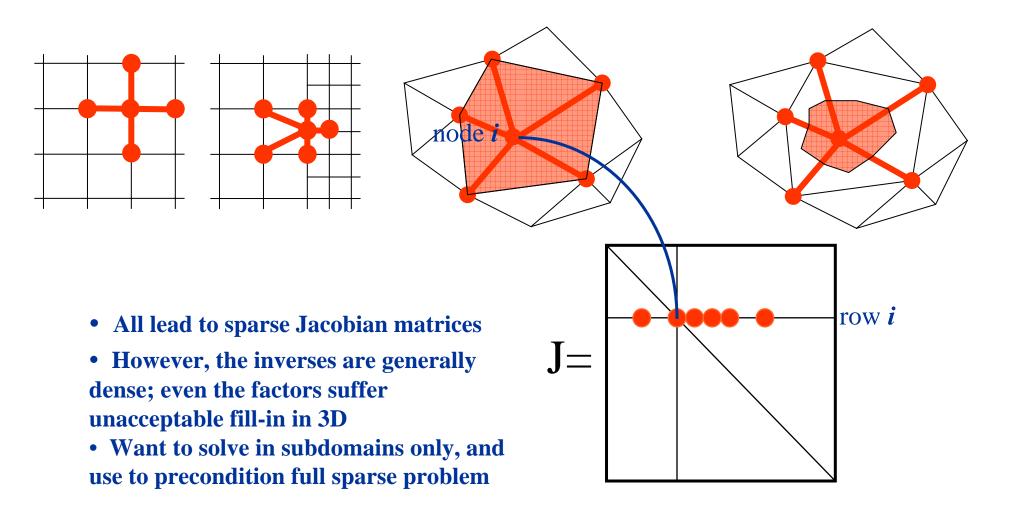

DD relevant to any local stencil formulation

finite differences

finite elements

finite volumes

Digression for notation's sake

 We need a convenient notation for mapping vectors (representing discrete samples of a continuous field) from full domain to subdomain and back

$$\begin{array}{c} u_1 \\ x_1 \\ x_2 \\ x_2 \\ x_4 \end{array} x_6$$

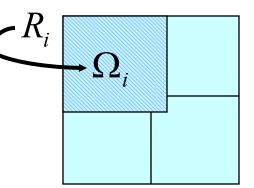

- Let *R_i* be a Boolean operator that extracts the elements of the *ith* subdomain from the global vector
- Then R_i^T maps the elements of the *i*th subdomain back into the global vector, padding with zeros

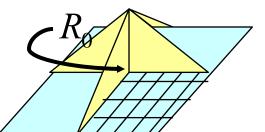

$$R_{1} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix} = \begin{bmatrix} x_{1} \\ x_{2} \\ x_{3} \\ x_{4} \\ x_{5} \\ x_{6} \end{bmatrix} = \begin{pmatrix} x_{1} \\ x_{2} \\ x_{3} \\ x_{4} \\ x_{5} \\ x_{6} \end{bmatrix} = u_{1}$$

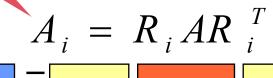

$$R_{1}^{T} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} = R_{1}^{T} u_{1} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} x_{1} \\ x_{3} \\ x_{4} \\ x_{5} \\ x_{6} \end{bmatrix} = u_{1}$$

Schwarz domain decomposition method

- Consider restriction and extension operators for subdomains, R_i, R_i^T , and for possible coarse grid, R_0, R_0^T
- Replace discretized Au = f with $B^{-1}Au = B^{-1}f$ $B^{-1} = R_0^T A_0^{-1} R_0 + \sum_i R_i^T A_i^{-1} R$
- Solve by a Krylov method
- Matrix-vector multiplies with
 - parallelism on each subdomain
 - nearest-neighbor exchanges, global reductions
 - possible small global system (not needed for parabolic case)

Krylov bases for sparse systems

- E.g., conjugate gradients (CG) for symmetric, positive definite systems, and generalized minimal residual (GMRES) for nonsymmetry or indefiniteness
- Krylov iteration is an algebraic projection method for converting a high-dimensional linear system into a lower-dimensional linear system

$$\begin{array}{cccc} H &\equiv W^T AV \\ Ax &= b \\ & = \end{array} \begin{array}{c} x = Vy \\ & = 1 \end{array} \begin{array}{c} Hy &= g \\ & = 1 \end{array} \begin{array}{c} g = W^T b \\ & = 1 \end{array} \begin{array}{c} g = W^T b \\ & = 1 \end{array} \end{array}$$

Remember this formula of Schwarz ...

For a "good" approximation, B^{-1} , to A^{-1} : $B^{-1} = \sum_{i} R_{i}^{T} (R_{i}AR_{i}^{T})^{-1}R_{i}$

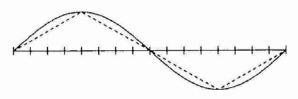

Now, let's compare!

- Operator decomposition (ADI)
 - natural row-based assignment requires *global all-toall, bulk* data exchanges in each step (for transpose)
- Function space decomposition (Fourier)
 - Natural mode-based assignment requires *global all-to-all, bulk* data exchanges in each step (for transform)
- Domain decomposition (Schwarz)
 - Natural domain-based assignment requires *local* surface data exchanges, global reductions, and optional small global problem

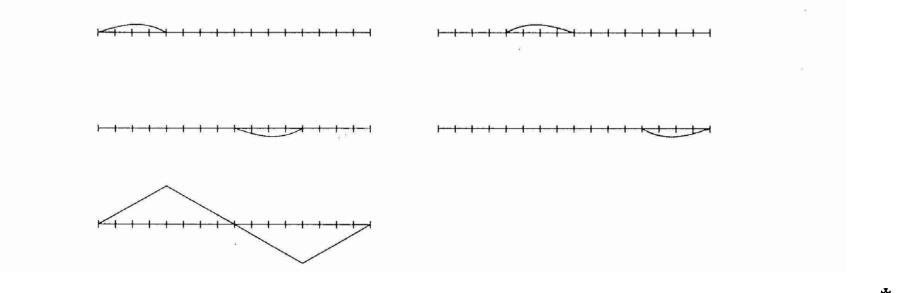

(Of course, domain decomposition can be interpreted as a *special* operator or function space decomposition)

Schwarz subspace decomposition

Consider a one-dimensional example. The function u(x) sketched below

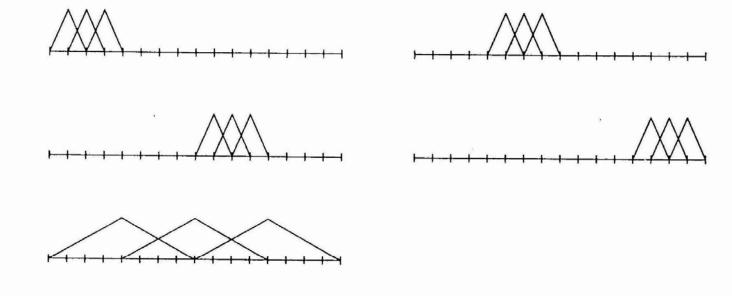

can be decomposed into the sum of the following five functions:

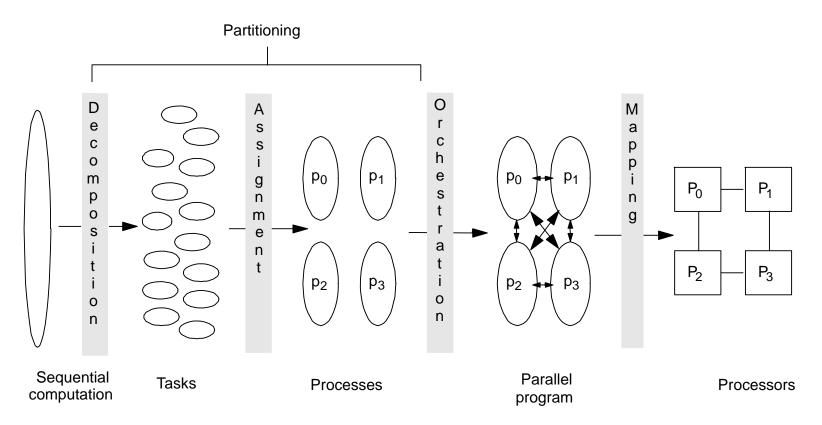

Schwarz subspace decomposition

Piecewise linear finite element bases for each of the five functions are shown below:

The first four of these subspaces are **mutually orthogonal**. The last one is **not orthogonal** to any of the others.

Four steps in creating a parallel program

- Decomposition of computation in tasks
- Assignment of tasks to processes
- Orchestration of data access, communication, synchronization
- Mapping processes to processors

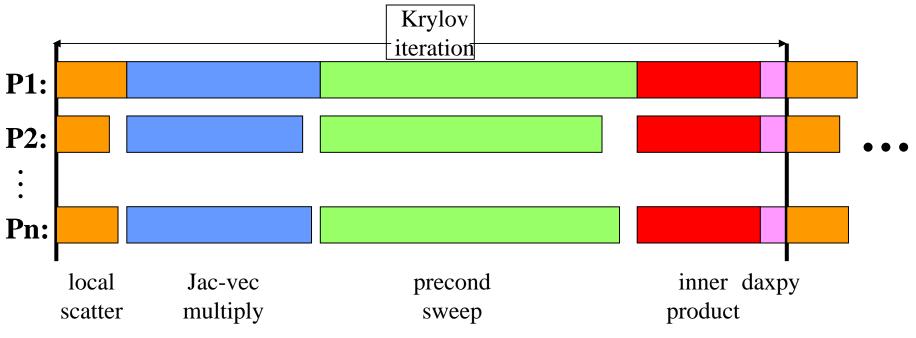

Krylov-Schwarz parallelization summary

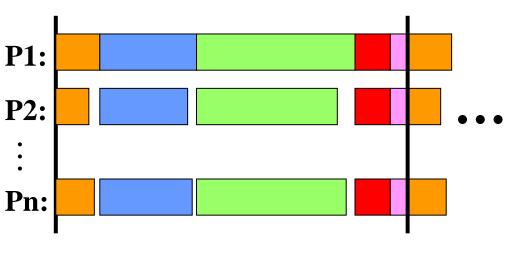

- Decomposition into concurrent tasks
 - by domain
- Assignment of tasks to processes
 - typically one subdomain per process
- Orchestration of communication between processes
 - to perform sparse matvec near neighbor communication
 - to perform subdomain solve nothing
 - to build Krylov basis global inner products
 - to construct best fit solution global sparse solve (redundantly)

- Mapping of processes to processors
 - typically one process per processor

Krylov-Schwarz kernel in parallel

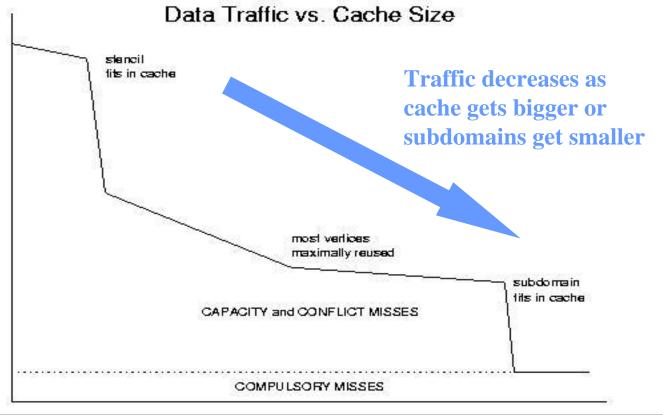

What happens if, for instance, in this (schematicized) iteration, arithmetic speed is *doubled*, scalar all-gather is **P2:** *quartered*, and local scatter is *cut by one-third*? Each phase is considered separately. Answer is to **Pn:** the right.

Krylov-Schwarz compelling in serial, too

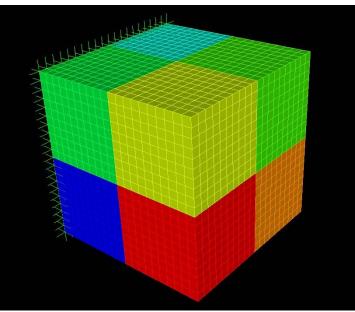

- As successive workingsets "drop" into a level of memory, capacity (and with effort conflict) misses disappear, leaving only compulsory misses, reducing demand on main memory bandwidth
- Cache size is not easily manipulated, but domain size *is*

Estimating scalability of stencil computations

- Given complexity estimates of the leading terms of:
 - the concurrent computation (per iteration phase)
 - the concurrent communication
 - the synchronization frequency
- And a bulk synchronous model of the architecture including:
 - internode communication (network topology and protocol reflecting horizontal memory structure)
 - on-node computation (effective performance parameters including vertical memory structure)
- One can estimate optimal concurrency and optimal execution time
 - on per-iteration basis, or overall (by taking into account any granularitydependent convergence rate)
 - simply differentiate time estimate in terms of (N,P) with respect to P, equate to zero and solve for P in terms of N

Estimating 3D stencil costs (per iteration)

- grid points in each direction n, total work N=O(n³)
- processors in each direction p, total procs P=O(p³)
- memory per node requirements O(N/P)

- concurrent execution time per iteration $A n^3/p^3$
- grid points on side of each processor subdomain *n/p*
- Concurrent neighbor commun. time per iteration $B n^2/p^2$
- cost of global reductions in each iteration $C \log p$ or $C p^{(1/d)}$
 - C includes synchronization frequency
- same dimensionless units for measuring *A*, *B*, *C*
 - e.g., cost of scalar floating point multiply-add

3D stencil computation illustration

Rich local network, tree-based global reductions

• total wall-clock time per iteration

$$T(n,p) = A\frac{n^3}{p^3} + B\frac{n^2}{p^2} + C\log p$$

• for optimal p , $\frac{\partial T}{\partial p} = 0$, or $-3A\frac{n^3}{p^4} - 2B\frac{n^2}{p^3} + \frac{C}{p} = 0$,

or (with
$$\theta = \frac{32B^3}{243A^2C}$$
),
 $p_{opt} = \left(\frac{3A}{2C}\right)^{\frac{1}{3}} \left(\left[1 + (1 - \sqrt{\theta})\right]^{\frac{1}{3}} + \left[1 - (1 - \sqrt{\theta})\right]^{\frac{1}{3}}\right) \cdot n$

- without "speeddown," \hat{p} can grow with n
- in the limit as $\frac{B}{C} \rightarrow 0$

$$p_{opt} = \left(\frac{3A}{C}\right)^{\frac{1}{3}} \cdot n$$

3D stencil computation illustration

Rich local network, tree-based global reductions

• optimal running time

$$T(n, p_{opt}(n)) = \frac{A}{\rho^{3}} + \frac{B}{\rho^{2}} + C\log(\rho n),$$

where

$$\rho = \left(\frac{3A}{2C}\right)^{\frac{1}{3}} \left(\left[1 + (1 - \sqrt{\theta})\right]^{\frac{1}{3}} + \left[1 - (1 - \sqrt{\theta})\right]^{\frac{1}{3}} \right)$$

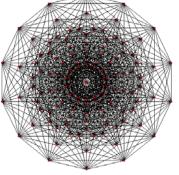

• limit of infinite neighbor bandwidth, zero neighbor latency $(B \rightarrow 0)$

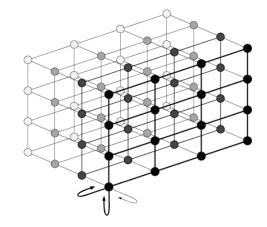

$$T(n, p_{opt}(n)) = C \left[\log n + \frac{1}{3} \log \frac{A}{C} + const \right]$$

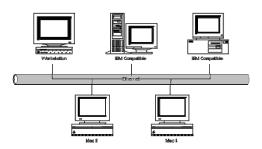

(This analysis is on a per iteration basis; complete analysis multiplies this cost by an iteration count estimate that generally depends on *n* and *p*.)

Scalability results for DD stencil computations

- With tree-based (logarithmic) global reductions and scalable nearest neighbor hardware:
 - optimal number of processors scales *linearly* with problem size
- With 3D torus-based global reductions and scalable nearest neighbor hardware:
 - optimal number of processors scales as *three-fourths* power of problem size (almost "scalable")
- With common network bus (heavy contention):
 - optimal number of processors scales as *one-fourth* power of problem size (not "scalable")

PDE varieties and complexities

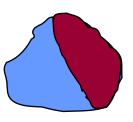

• Evolution (time hyperbolic, time parabolic)

$$\frac{\partial}{\partial t}(\bullet) + \nabla \cdot (f(\bullet)) = \dots, \quad \frac{\partial}{\partial t}(\bullet) - \nabla \cdot (\alpha \nabla \bullet) = \dots$$

• Equilibrium (*elliptic, spatially hyperbolic or parabolic*)

$$\nabla \cdot (U \bullet - \alpha \nabla \bullet) = \dots$$

- Mixed, varying by region
- Mixed, of multiple type (e.g., parabolic with elliptic constraint)

Explicit PDE solvers

$$\mathbf{u}^{l} = \mathbf{u}^{l-1} - \Delta t^{l} \bullet f(\mathbf{u}^{l-1})$$

- Concurrency is pointwise, *O(N)*
- Comm.-to-Comp. ratio is surface-to-volume, O((N/P)^{-1/3})
- Communication range is nearest-neighbor, except for time-step computation
- Synchronization frequency is once per step, *O((N/P)⁻¹)*
- Storage per point is low
- Load balance is straightforward for static quasi-uniform grids
- Grid adaptivity (together with temporal stability limitation) makes load balance nontrivial

Domain-decomposed implicit PDE solvers u^{l} u^{l-1} l

$$\frac{\mathbf{u}}{\Delta t^{l}} + f(\mathbf{u}^{l}) = \frac{\mathbf{u}}{\Delta t^{l}}, \Delta t^{l} \to \infty$$

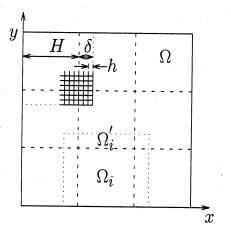

- Concurrency is pointwise, *O(N)*, or subdomainwise, *O(P)*
- Comm.-to-Comp. ratio still *mainly* surface-to-volume, *O((N/P)^{-1/3})*
- Communication still *mainly* nearest-neighbor, but nonlocal communication arises from conjugation, norms, coarse grid problems
- Synchronization frequency *often more* than once per gridsweep, up to Krylov dimension, *O(K(N/P)⁻¹)*
- Storage per point is higher, by factor of *O(K)*
- Load balance issues the same as for explicit

Resource scaling for PDEs

- For 3D problems, work is proportional to four-thirds power of memory, because
 - for equilibrium problems, work scales with problem size times number of iteration steps -- proportional to resolution in single spatial dimension
 - for evolutionary problems, work scales with problems size times number of time steps -- CFL arguments place latter on order of spatial resolution, as well
- Proportionality constant can be adjusted over a very wide range by both discretization (high-order implies more work per point and per memory transfer) and by algorithmic tuning
- Machines designed for PDEs can be "memory-thin"
- If frequent time frames are to be captured, other resources -- disk capacity and I/O rates -- must both scale linearly with work, more stringently than for memory.

Factoring convergence rate into estimates

- Krylov-Schwarz iterative methods typically converge in a number of iterations that scales as the square-root of the condition number of the Schwarz-preconditioned system
- In terms of *N* and *P*, where for *d*-dimensional isotropic problems, *N*=*h*^{-*d*} and *P*=*H*^{-*d*}, for mesh parameter *h* and subdomain diameter *H*, iteration counts may be estimated as follows:

Preconditioning Type	in 2D	in 3D
Point Jacobi	O (N ^{1/2})	O (N ^{1/3})
Domain Jacobi (δ=0)	O((NP) ^{1/4})	O((NP) ^{1/6})
1-level Additive Schwarz	O(P ^{1/2})	O(P ^{1/3})
2-level Additive Schwarz	O(1)	O(1)

Where do these results come from?

- Point Jacobi result is well known (see any book on the numerical analysis of elliptic problems)
- Subdomain Jacobi result has interesting history
 - Was derived independently from functional analysis, linear algebra, and graph theory
- Schwarz theory is neatly and abstractly summarized in Section 5.2 Smith, Bjorstad & Gropp (1996) and Chapter 2 of Toselli & Widlund (2004)
 - condition number, $\kappa \leq \omega [1 + \rho(\mathcal{E})] C_0^2$
 - C_0^2 is a splitting constant for the subspaces of the decomposition
 - $\rho(\mathcal{E})$ is a measure of the orthogonality of the subspaces
 - ω is a measure of the approximation properties of the subspace solvers (can be unity for exact subdomain solves)
 - These properties are estimated for different subspaces, different operators, and different subspace solvers and the "crank" is turned

Comments on the Schwarz results

- Original basic Schwarz estimates were for:
 - self-adjoint elliptic operators
 - positive definite operators
 - *exact* subdomain solves, A_i^{-1}
 - *two-way* overlapping with R_i, R_i^T
 - *generous* overlap, $\delta = O(H)$ (original 2-level result was $O(1+H/\delta)$)
- Subsequently extended to (within limits):
 - nonself-adjointness (e.g, convection)
 - indefiniteness (e.g., wave Helmholtz)
 - *inexact* subdomain solves
 - one-way overlap communication ("restricted additive Schwarz")
 - *small* overlap

Comments on the Schwarz results, cont.

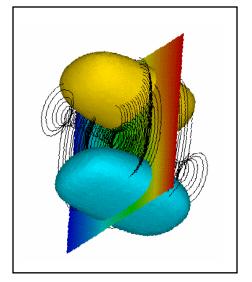

- Theory still requires "sufficiently fine" coarse mesh
 - However, coarse space need *not* be nested in the fine space or in the decomposition into subdomains
- Practice is better than one has any right to expect

"In theory, theory and practice are the same ... In practice they're not!" — Yogi Berra

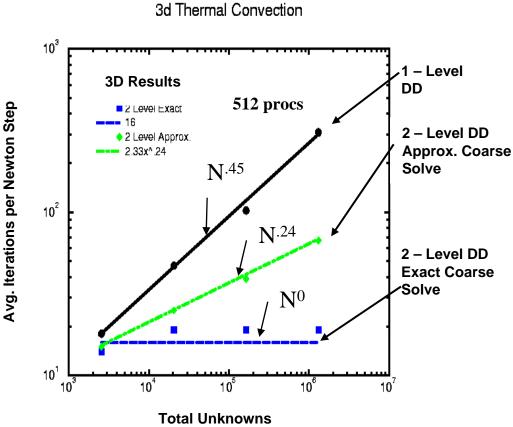

- Wave Helmholtz (e.g., acoustics) is delicate at high frequency:
 - standard Schwarz Dirichlet boundary conditions can lead to undamped resonances within subdomains, $u_{\Gamma} = 0$
 - remedy involves Robin-type transmission boundary conditions on subdomain boundaries, $(u + \alpha \partial u / \partial n)_{\Gamma} = 0$

Illustration of 1-level vs. 2-level tradeoff

"Unreasonable effectiveness" of Schwarz

• When does the sum of partial inverses equal the inverse of the sums? When the decomposition is right! Let $\{r_i\}$ be a complete set of orthonormal row eigenvectors for A: $r_i A = a_i r_i$ or $a_i = r_i A r_i^T$

Then

$$A = \sum_{i} r_i^T a_i r_i$$

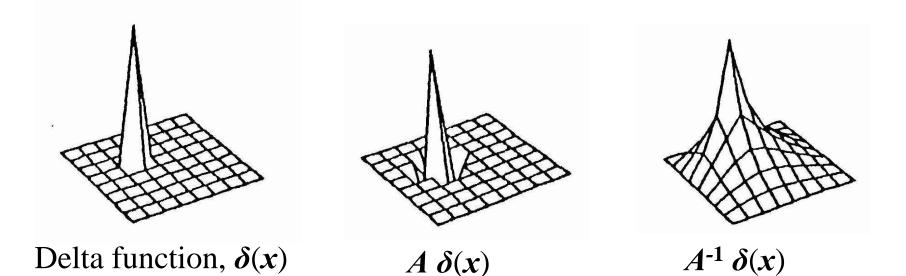

and

$$A^{-1} = \sum_{i} r_{i}^{T} a_{i}^{-1} r_{i} = \sum_{i} r_{i}^{T} (r_{i} A r_{i}^{T})^{-1} r_{i}$$

— the Schwarz formula!

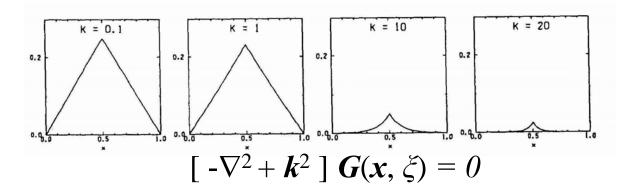

• Good decompositions are a compromise between conditioning and parallel complexity, in practice

"Unreasonable effectiveness" of Schwarz, cont.

- Forward Poisson operator is localized and sparse
- Inverse operator is *locally concentrated*, but dense
- A coarse grid is necessary (and sufficient, for good conditioning) to represent the coupling between a field point and its forcing coming from nonlocal regions

"Unreasonable effectiveness" of Schwarz, cont.

- Green's functions for the "good Helmholtz" operator on the unit interval, shown with four increasing diagonal shifts, for $\xi = 0.5$
- It is intuitively clear why the diagonally dominant case is easy to precondition without a coarse grid
- This corresponds to the implicitly differenced parabolic system, and arises commonly in practice

- Given a partition
- Condense:

$$\begin{bmatrix} A_{ii} & A_{i\Gamma} \\ A_{\Gamma i} & A_{\Gamma\Gamma} \end{bmatrix} \begin{bmatrix} u_i \\ u_{\Gamma} \end{bmatrix} = \begin{bmatrix} f_i \\ f_{\Gamma} \end{bmatrix}$$

$$Su_{\Gamma} = g \qquad S \equiv A_{\Gamma\Gamma} - A_{\Gamma i} A_{ii}^{-1} A_{i\Gamma} \quad g \equiv f_{\Gamma} - A_{\Gamma i} A_{ii}^{-1} f_i$$

- **Properties of the Schur complement:**
 - smaller than original A, but generally dense
 - expensive to form, to store, to factor, and to solve
 - better conditioned than original A, for which $\kappa(A) = O(h^{-2})$
 - for a single interface, $\kappa(S) = O(h^{-1})$
- Therefore, solve iteratively, with action of S on each Krylov vector

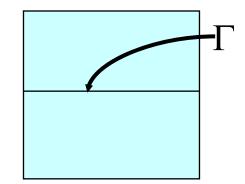

• Note the factorization of the system matrix

$$A = \begin{bmatrix} A_{ii} & 0 \\ A_{\Gamma i} & I \end{bmatrix} \begin{bmatrix} I & A_{ii}^{-1}A_{i\Gamma} \\ 0 & S \end{bmatrix}$$

• Hence a perfect preconditioner is

$$A^{-1} = \begin{bmatrix} I & A_{ii}^{-1}A_{i\Gamma} \\ 0 & S \end{bmatrix}^{-1} \begin{bmatrix} A_{ii} & 0 \\ A_{\Gamma i} & I \end{bmatrix}^{-1} \\ = \begin{bmatrix} I & -A_{ii}^{-1}A_{i\Gamma}S^{-1} \\ 0 & S^{-1} \end{bmatrix} \begin{bmatrix} A_{ii}^{-1} & 0 \\ -A_{\Gamma i}A_{ii}^{-1} & I \end{bmatrix}$$

- Let M^{-1} be any good preconditioner for S
- Let $B^{-1} = \begin{bmatrix} I & \widetilde{A}_{ii}^{-1}A_{i\Gamma} \\ 0 & M \end{bmatrix}^{-1} \begin{bmatrix} \widetilde{A}_{ii} & 0 \\ A_{\Gamma i} & I \end{bmatrix}^{-1}$

• Then *B*⁻¹ is a good preconditioner for *A*, for recall

$$A^{-1} = \begin{bmatrix} I & A_{ii}^{-1} A_{i\Gamma} \\ 0 & S \end{bmatrix}^{-1} \begin{bmatrix} A_{ii} & 0 \\ A_{\Gamma i} & I \end{bmatrix}^{-1}$$

• So, instead of $M^{-1}Su_{\Gamma} = M^{-1}g$, use full system

$$B^{-1}\begin{bmatrix} A_{ii} & A_{i\Gamma} \\ A_{\Gamma i} & A_{\Gamma\Gamma} \end{bmatrix} \begin{bmatrix} u_i \\ u_{\Gamma} \end{bmatrix} = B^{-1}\begin{bmatrix} f_i \\ f_{\Gamma} \end{bmatrix}$$

- Here, solves with A_{ii} may be done approximately since all degrees of freedom are retained
- Once this simple block decomposition is understood, everything boils down to two more profound questions:
 - How to approximate *S* cheaply
 - How should the relative quality of M and A_{ii} compare

- How to approximate *S* cheaply?
 - Many techniques for a single interface
 - Factorizations of narrow band approximations
 - Spectral (FFT-implementable) decompositions
 - Algebraic "probing" of a specified sparsity pattern for inverse
- For separator sets more complicated than a single interface, we componentize, creating the preconditioner of the union from the sum of preconditioners of the individual pieces

- Beyond a simple interface, preconditioning the Schur complement is complex in and of itself; Schwarz is used on the reduced problem
- Neumann-Neumann

$$M^{-1} = \Sigma_i D_i R_i^T S_i^{-1} R_i D_i$$

- Balancing Neumann-Neumann $M^{-1} = M_0^{-1} + (I - M_0^{-1}S)(\Sigma_i D_i R_i^T S_i^{-1} R_i D_i)(I - SM_0^{-1})$
- *Numerous* other variants allow inexact subdomain solves, combining additive Schwarz-like preconditioning of the separator set components with inexact subdomain solves on the subdomains

• As an illustration of the algorithmic structure, we consider the 2D Bramble-Pasciak-Schatz (1984) preconditioner for the case of many subdomains

Ω_1	$Ω_2$ vertex			$\begin{bmatrix} A_{II} & A_{IB} \\ A_{IB}^T & A_{BB} \end{bmatrix} \begin{bmatrix} u_I \\ u_B \end{bmatrix} = \begin{bmatrix} f_I \\ f_B \end{bmatrix}$
	V_m	(x_k^H, y_k^H)		$A_{II} = \text{blockdiag}\left(A_{ii}\right) = \begin{bmatrix} A_{11} & 0 \\ & \ddots \end{bmatrix}$
a vertex	subregion	Ω_j an edge	Ω_i E_{ij}	0 A _{pp}

- For this case $\kappa(S) = O(H^{-1}h^{-1})$, which is not as good as the single interface case, for which $\kappa(S) = O(h^{-1})$
- The Schur complement has the block structure

$$S = \begin{bmatrix} S_{EE} & S_{EV} \\ S_{EV}^T & S_{VV} \end{bmatrix}$$

for which the following block diagonal preconditioner improves conditioning only to $O(H^{-2} \log^2(Hh^{-1}))$

$$M^{-1} = \begin{bmatrix} S_{EE}^{-1} & 0 \\ 0 & S_{VV}^{-1} \end{bmatrix}$$

• Note that we can write M^{-1} equivalently as $M^{-1} = \sum_{i} R_{E_{i}}^{T} S_{E_{i}E_{i}}^{-1} R_{E_{i}} + \sum_{j} R_{V_{j}}^{T} S_{V_{j}V_{j}}^{-1} R_{V_{j}}$

• If we replace the diagonal vertex term of *M*⁻¹ with a coarse grid operator

$$M^{-1} = \sum_{i} R_{E_{i}}^{T} S_{E_{i}E_{i}}^{-1} R_{E_{i}} + R_{H}^{T} A_{H}^{-1} R_{H}$$

then

$$\kappa(M^{-1}S) = C(1 + \log^2(Hh^{-1}))$$

where *C* may still retain dependencies on other bad parameters, such as jumps in the diffusion coefficients

- The edge term can be replaced with cheaper components
- There are numerous variations in 2D and 3D that conquer various additional weaknesses

Schwarz polynomials

- Polynomials of Schwarz projections that are combinations of additive and multiplicative may be appropriate for certain implementations
- We may solve the fine subdomains concurrently and follow with a coarse grid (redundantly/cooperatively)

$$u \leftarrow u + \Sigma_i B_i^{-1} (f - Au)$$
$$u \leftarrow u + B_0^{-1} (f - Au)$$

• This leads to algorithm "Hybrid II" in S-B-G'96:

$$B^{-1} = B_0^{-1} + (I - B_0^{-1}A)(\Sigma_i B_i^{-1})$$

• Convenient for "SPMD" (single prog/multiple data)

Onward to nonlinearity

• Linear versus nonlinear problems

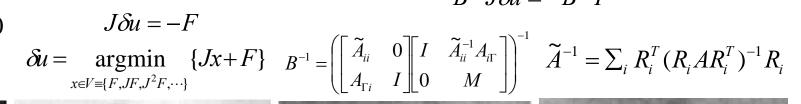

- Solving linear algebraic problems often constitutes 90% of the running time of a large simulation
- The nonlinearity is often a fairly straightforward outer loop, in that it introduces no new types of messages or synchronizations, and has overall many fewer synchronizations than the preconditioned Krylov method or other linear solver inside it
- We can wrap Newton, Picard, fixed-point or other iterations outside, linearize, and apply what we know
- We consider both Newton-outside and Newton-inside methods

Newton-Krylov-Schur-Schwarz: a solver "workhorse"

 $B^{-1}J\delta u = -B^{-1}F$

$$F(u) \approx F(u_c) + F'(u_c) \delta u = 0$$
$$u = u_c + \lambda \, \delta u$$

Newton nonlinear solver *asymptotically quadratic* Krylov accelerator spectrally adaptive

Schur preconditioner parallelizable by structure Schwarz preconditioner *parallelizable by domain*

Newton's Method

• Given $F(u) = 0, F : \Re^n \to \Re^n$ and iterate u^0 we wish to pick u^{k+1} such that

$$F(u^{k+1}) \approx F(u^{k}) + F'(u^{k})\delta u^{k} = 0$$

where $\delta u^{k} = u^{k+1} - u^{k}, k = 0, 1, 2, ...$

- Neglecting higher-order terms, we get $\delta u^{k} = -[J(u^{k})]^{-1}F(u^{k})$ where $J = F'(u^{k})$ is the Jacobian matrix, generally large, sparse, and ill-conditioned for PDEs
- In practice, require $|| F(u^k) + J(u^k) \delta u^k || < \varepsilon$
- In practice, set $u^{k+1} = u^k + \lambda \delta u^k$ where λ is selected to minimize $|| F(u^k + \lambda \delta u^k) ||$

Krylov Method

- Given Ax = b, $A \in \Re^{n \times n}$ and iterate x^0 , we wish to generate a basis $V = \{v_1, v_2, ..., v_k\} \in \Re^{n \times k}$ for x $(x \approx Vy)$ and a set of coefficients $\{y_1, y_2, ..., y_k\}$ such that x^k is a best fit in the sense that $y \in \Re^{-k}$ minimizes ||AVy - b||
- Krylov methods are algebraic Petrov-Galerkin methods that define a complementary basis W = {w₁, w₂,..., w_k} ∈ ℜ^{n×k} so that W^T (AVy - b) = 0 may be solved for y
- In practice k << n and the bases are grown from seed vector r⁰ = Ax⁰ b via recursive multiplication by A and Gram-Schmidt

Newton-Krylov-Schwarz

for (k = 0; k < n_Newton; k++) { compute nonlinear residual and Jacobian for (j = 0; j < n_Krylov; j++) { forall (i = 0; i < n_Precon ; i++) { solve subdomain problems concurrently } // End of loop over subdomains Newton Krylov perform Jacobian-vector product loop loop enforce Krylov basis conditions update optimal coefficients check linear convergence } // End of linear solver perform DAXPY update check nonlinear convergence } // End of nonlinear loop

Jacobian-free Newton-Krylov

- In the Jacobian-Free Newton-Krylov (JFNK) method, a Krylov method solves the linear Newton correction equation, requiring Jacobian-vector products
- These are approximated by the Fréchet derivatives

$$J(u)v \approx \frac{1}{\varepsilon} [F(u + \varepsilon v) - F(u)]$$

(where \mathcal{E} is chosen with a fine balance between approximation and floating point rounding error) or automatic differentiation, so that the actual Jacobian elements are *never explicitly needed*

• One builds the Krylov space on a true *F'(u)* (to within numerical approximation)

How to accommodate preconditioning

• Krylov iteration is expensive in memory and in function evaluations, so subspace dimension *k* must be kept small in practice, through preconditioning the Jacobian with an approximate inverse, so that the product matrix has low condition number in

$$(B^{-1}A)x = B^{-1}b$$

• Given the ability to apply the action of B^{-1} to a vector, preconditioning can be done on either the left, as above, or the right, as in, e.g., for matrix-free:

$$JB^{-1}v \approx \frac{1}{\varepsilon} [F(u + \varepsilon B^{-1}v) - F(u)]$$

Philosophy of Jacobian-free NK

- To *evaluate* the linear residual, we use the true *F*'(*u*), giving a true Newton step and asymptotic quadratic Newton convergence
- To *precondition* the linear residual, we do anything convenient that uses understanding of the dominant physics/mathematics in the system and respects the limitations of the parallel computer architecture and the cost of various operations:
 - Jacobian blocks decomposed for parallelism (Schwarz)
 - Jacobian of lower-order discretization
 - Jacobian with "lagged" values for expensive terms
 - Jacobian stored in lower precision
 - Jacobian of related discretization
 - operator-split Jacobians
 - physics-based preconditioning

Nonlinear Schwarz preconditioning

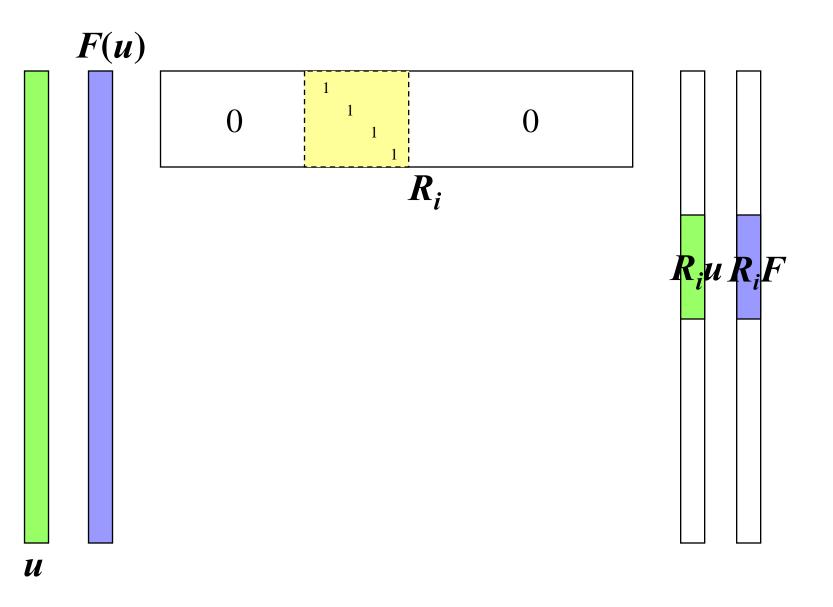

- Nonlinear Schwarz has Newton both *inside* and *outside* and is fundamentally Jacobian-free
- It replaces F(u) = 0 with a new nonlinear system possessing the same root, $\Phi(u) = 0$
- Define a correction $\delta_i(u)$ to the i^{th} partition (e.g., subdomain) of the solution vector by solving the following local nonlinear system:

 $R_i F(u + \delta_i(u)) = 0$

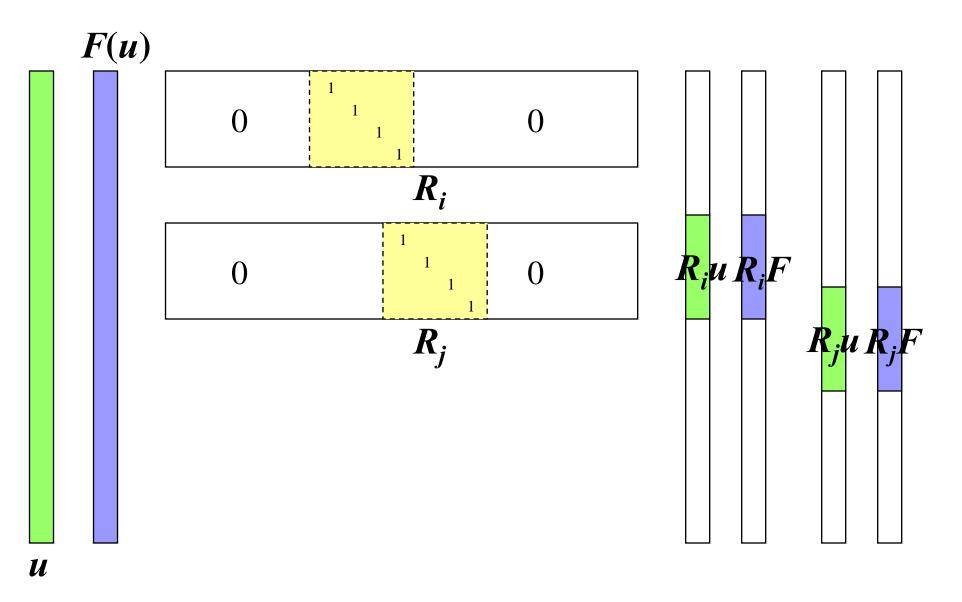

where $\delta_i(u) \in \Re^n$ is nonzero only in the components of the i^{th} partition

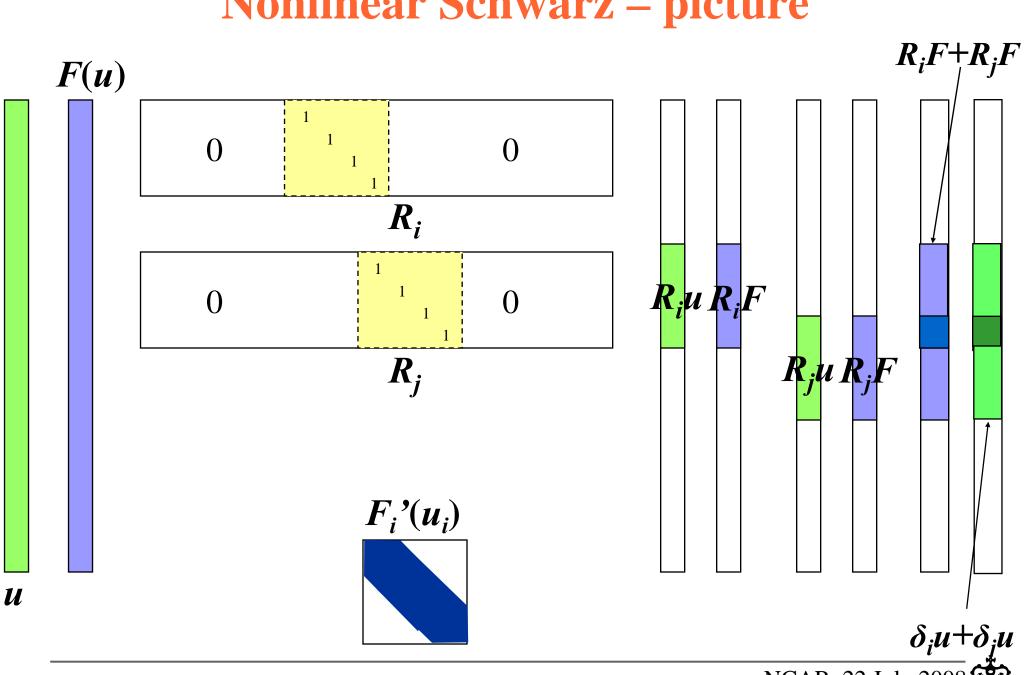

• Then sum the corrections: $\Phi(u) = \sum_i \delta_i(u)$ to get an implicit function of u

Nonlinear Schwarz – picture

Nonlinear Schwarz – picture

Nonlinear Schwarz – picture

Nonlinear Schwarz, cont.

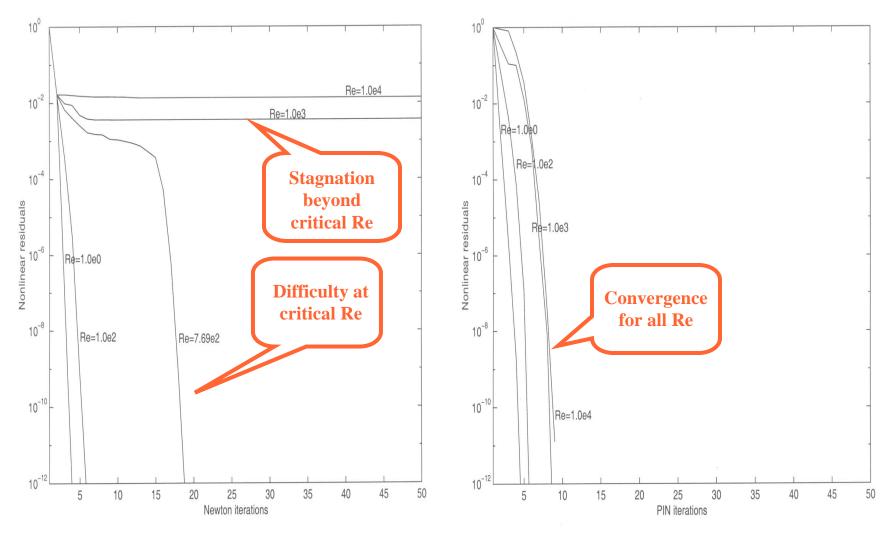

- It is simple to prove that if the Jacobian of F(u) is nonsingular in a neighborhood of the desired root then Φ(u) = 0 and F(u) = 0 have the same unique root
- To lead to a Jacobian-free Newton-Krylov algorithm we need to be able to evaluate for any *u*, *v* ∈ ℜⁿ :
 - The residual $\Phi(u) = \sum_i \delta_i(u)$
 - The Jacobian-vector product $\Phi(u)'_V$
- Remarkably, (Cai-Keyes, 2000) it can be shown that $\Phi'(u) v \approx \sum_{i} (R_{i}^{T} J_{i}^{-1} R_{i}) Jv$ where J = F'(u) and $J_{i} = R_{i} J R_{i}^{T}$
- All required actions are available in terms of F(u) !

Driven cavity in velocity-vorticity coords

cold
wrelocity
$$-\nabla^2 u - \frac{\partial \omega}{\partial y} = 0$$

hot y -velocity $-\nabla^2 v + \frac{\partial \omega}{\partial x} = 0$
vorticity $-\nabla^2 \omega + u \frac{\partial \omega}{\partial x} + v \frac{\partial \omega}{\partial y} - \operatorname{Gr} \frac{\partial T}{\partial x} = 0$
internal energy $-\nabla^2 T + \Pr(u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y}) = 0$

Experimental example of nonlinear Schwarz

Vanilla Newton's method

Nonlinear Schwarz

Multiphysics coupling: partial elimination

• Consider system F(u) = 0 partitioned by physics as

$$F_1(u_1, u_2) = 0$$
$$F_2(u_1, u_2) = 0$$

• **Can formally solve for** u_1 **in** $F_1(u_1, u_2) = 0$

$$u_1 \equiv G(u_2)$$

- Then second equation is $F_2(G(u_2), u_2) = 0$
- Jacobian

$$\frac{dF_2}{du_2} = \frac{\partial F_2}{\partial u_1} \frac{\partial G}{\partial u_2} + \frac{\partial F_2}{\partial u_2}$$

can be applied to a vector in matrix-free manner

Multiphysics coupling: nonlinear GS

- In previous notation, given initial iterate $\{u_1^0, u_2^0\}$
- For *k*=1, 2, ..., until convergence, do
 - Solve for *v* in $F_1(v, u_2^{k-1}) = 0$
 - Solve for w in $F_2(v, w) = 0$
- Then

$$\left\{u_1^k, u_2^k\right\} = \left\{v, w\right\}$$

Multiphysics coupling: nonlinear Schwarz

- **Given initial iterate** $\{u_1^0, u_2^0\}$
- For k=1, 2, ..., until convergence, do
 - Define $G_1(u_1, u_2) \equiv \delta u_1$ by $F_1(u_1^{k-1} + \delta u_1, u_2^{k-1}) = 0$
 - Define $G_2(u_1, u_2) \equiv \delta u_2$ by $F_2(u_1^{k-1}, u_2^{k-1} + \delta u_2) = 0$

• Then solve

$$\begin{cases} G_1(u,v) = 0 & \text{in matrix-free manner} \\ G_2(u,v) = 0 \end{cases}$$

• Jacobian: $\begin{bmatrix} \frac{\partial G_1}{\partial u} & \frac{\partial G_1}{\partial v} \\ \frac{\partial G_2}{\partial u} & \frac{\partial G_2}{\partial v} \end{bmatrix} \approx \begin{bmatrix} I & \left(\frac{\partial F_1}{\partial u}\right)^{-1} \frac{\partial F_1}{\partial v} \\ \left(\frac{\partial F_2}{\partial v}\right)^{-1} \frac{\partial F_2}{\partial u} & I \end{bmatrix}$ • Finally $\{u_1^k, u_2^k\} = \{v, w\}$

Constrained optimization w/Lagrangian

- Consider Newton's method for solving the nonlinear rootfinding problem derived from the necessary conditions for constrained optimization
- **Constraint** $c(x,u) = 0 ; x \in \Re^N; u \in \Re^M; c \in \Re^N$
- **Objective** $\min_{u} f(x,u); f \in \Re$
- Lagrangian $f(x, u) + \lambda^T c(x, u); \lambda \in \Re^N$
- Form the gradient of the Lagrangian with respect to each of *x*, *u*, and λ:

$$f_x(x,u) + \lambda^T c_x(x,u) = 0$$
$$f_u(x,u) + \lambda^T c_u(x,u) = 0$$
$$c(x,u) = 0$$

Newton on first-order conditions

• Equality constrained optimization leads to the KKT system for states x, designs u, and multipliers λ

$$\begin{bmatrix} W_{xx} & W_{ux}^T & J_x^T \\ W_{ux} & W_{uu} & J_u^T \\ J_x & J_u & 0 \end{bmatrix} \begin{bmatrix} \delta x \\ \delta u \\ \delta \lambda \end{bmatrix} = -\begin{bmatrix} g_x \\ g_u \\ c \end{bmatrix}$$

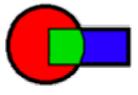

• Newton Reduced SQP solves the Schur complement system $H \,\delta u = g$, where H is the reduced Hessian $H = W_{uv} - J_u^T J_x^{-T} W_{ux}^T - (J_u^T J_x^{-T} W_{xx} - W_{ux}) J_x^{-1} J_u$ $g = -g_u + J_u^T J_x^{-T} g_x - (J_u^T J_x^{-T} W_{xx} - W_{ux}) J_x^{-1} c$ • Then $J_x \delta x = -c - J_u \delta u$ $J_x^T \delta \lambda = -g_x - W_{xx} \delta x - W_{ux}^T \delta u$

RSQP when constraints are PDEs

- Problems
- J_x is the Jacobian of a PDE \Rightarrow huge!
 - $W_{\alpha\beta}$ involve Hessians of objective and constraints \Rightarrow second derivatives and huge
 - *H* is unreasonable to form, store, or invert
- Proposed solution: Schwarz inside Schur!
 - form approximate inverse action of state Jacobian and its transpose in parallel by Schwarz/multilevel methods
 - form forward action of Hessians by automatic differentiation; exact action needed only on vectors (JFNK)
 - do not eliminate exactly; use Schur preconditioning on *full* system

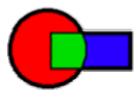

State of the art

- Domain decomposition is the dominant paradigm in contemporary terascale PDE simulation
- Several freely available software toolkits exist, and successfully scale to thousands of tightly coupled processors for problems on quasi-static meshes
- Concerted efforts underway to make elements of these toolkits interoperate, and to allow expression of the best methods, which tend to be modular, hierarchical, recursive, and above all *adaptive*!
- Many challenges loom at the "next scale" of computation
- Implementation of domain decomposition methods on parallel computers has inspired many useful variants of domain decomposition methods
- The past few years have produced an incredible variety of interesting results (in both the continuous and the discrete senses) in domain decomposition methods, with no slackening in sight
