The Madison Dynamo Experiment

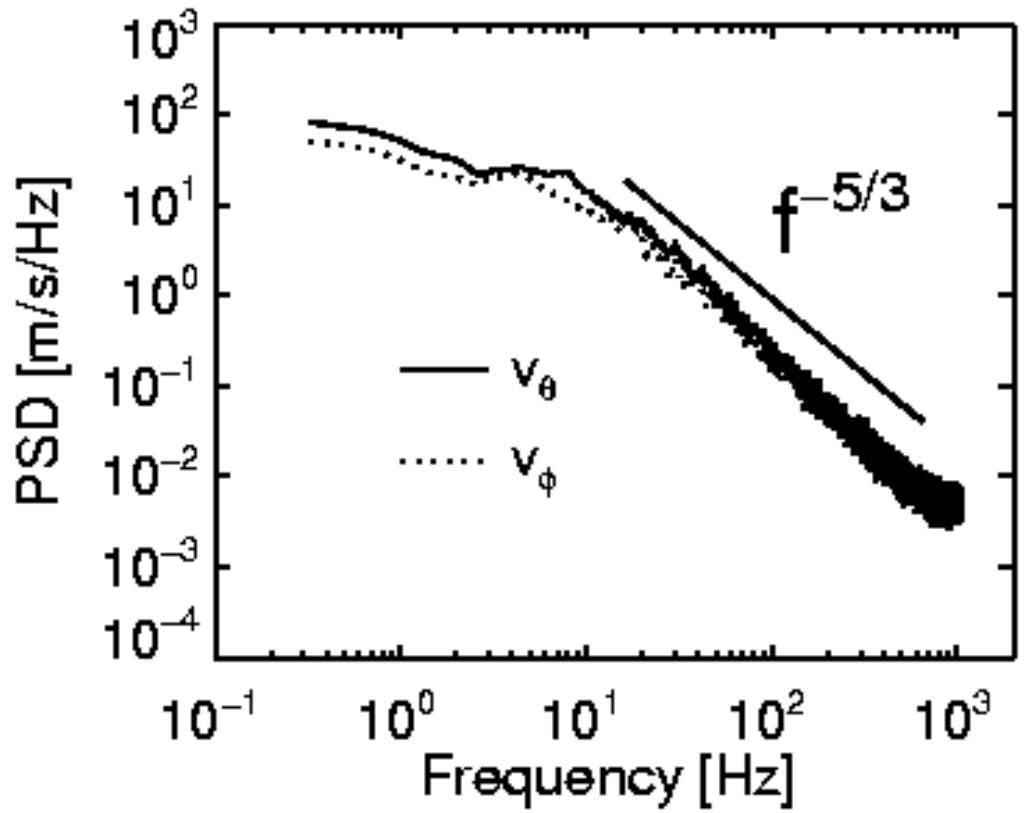

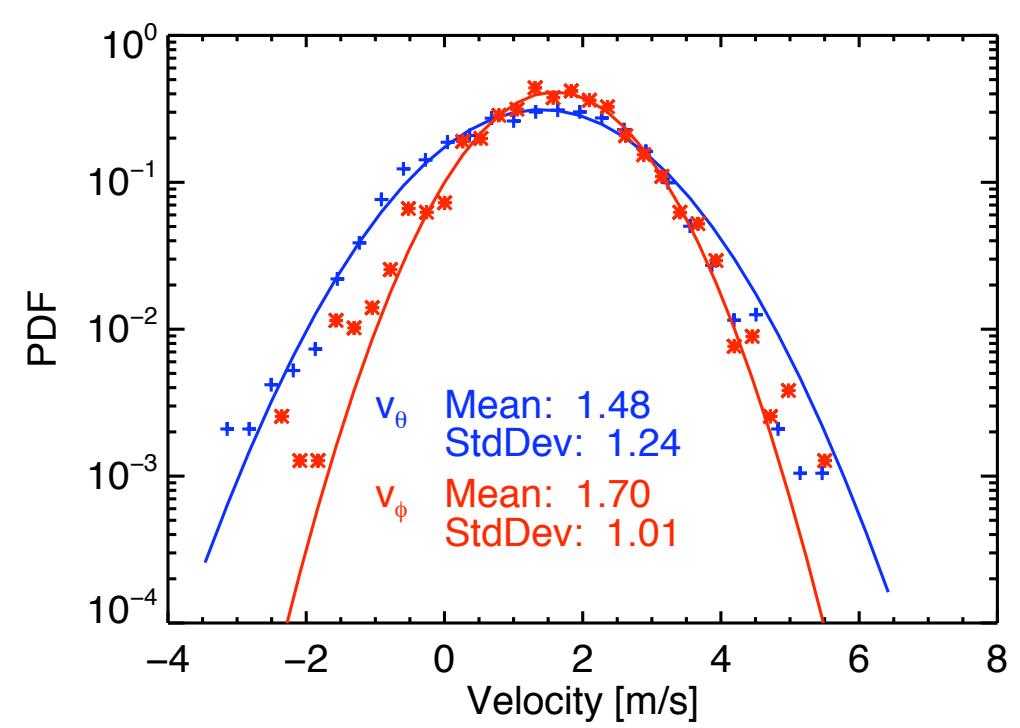

- 1 meter diameter sphere
- 180 gallons liquid sodium
- Two 75 kW motors drive impellers (30 Hz max)
- External coils create a nearly uniform magnetic field coaxial with the symmetry axis
- 74 Hall probes on surface of sphere to measure field

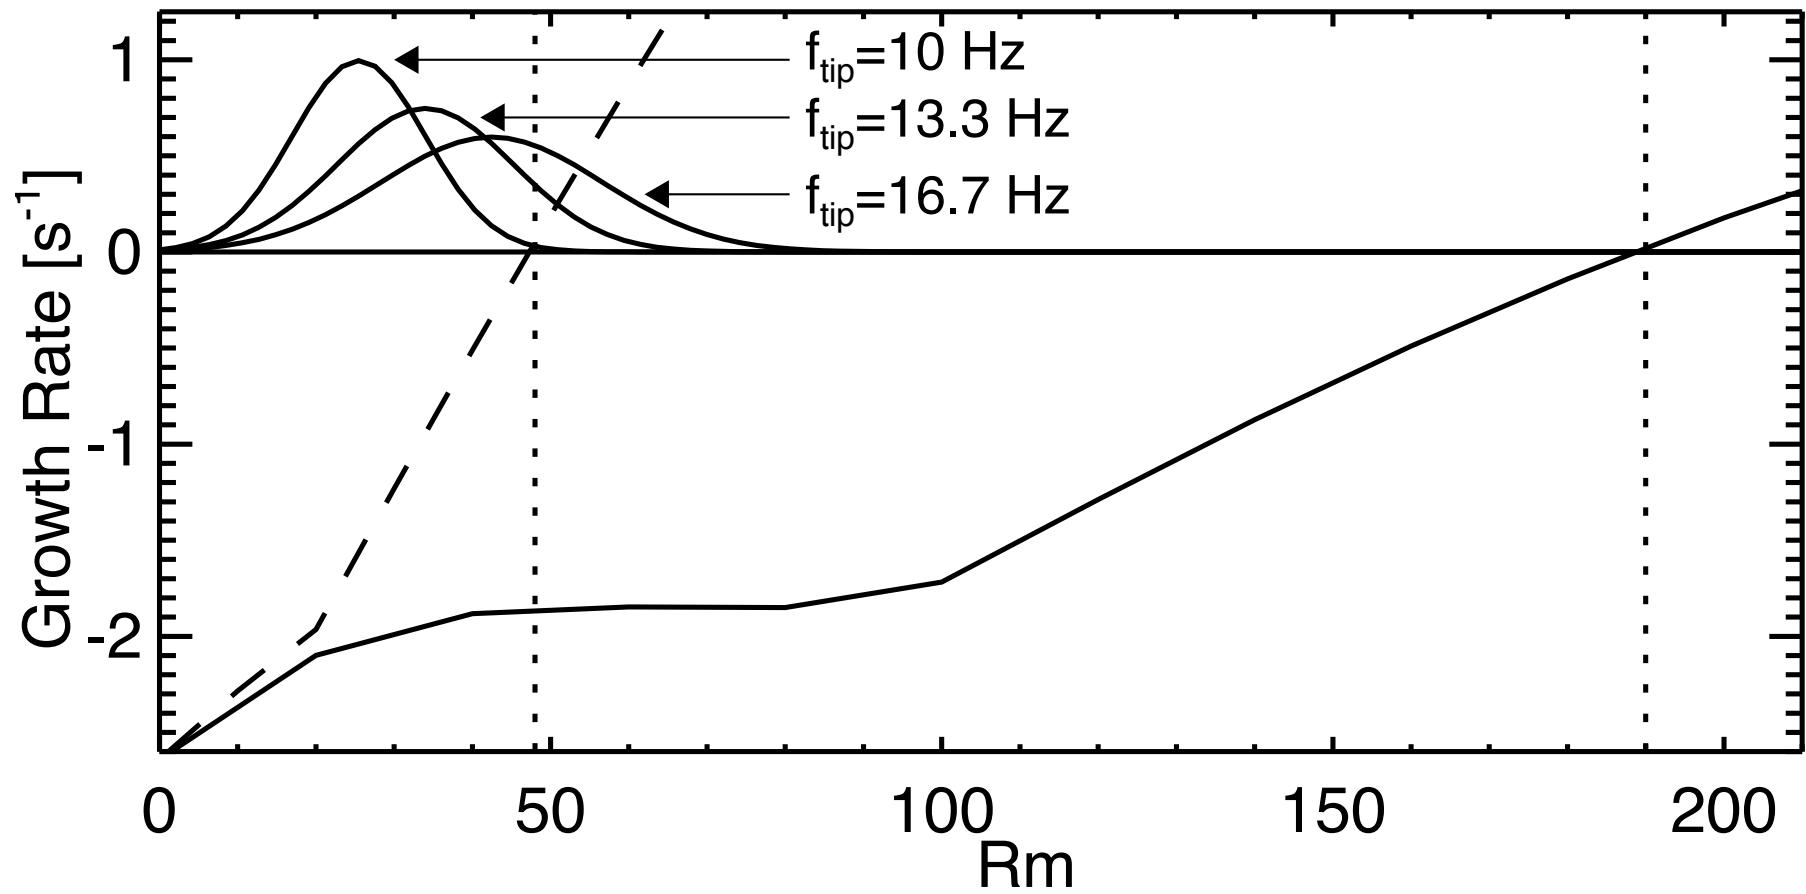

Mean velocity field model constructed from LDV measurements

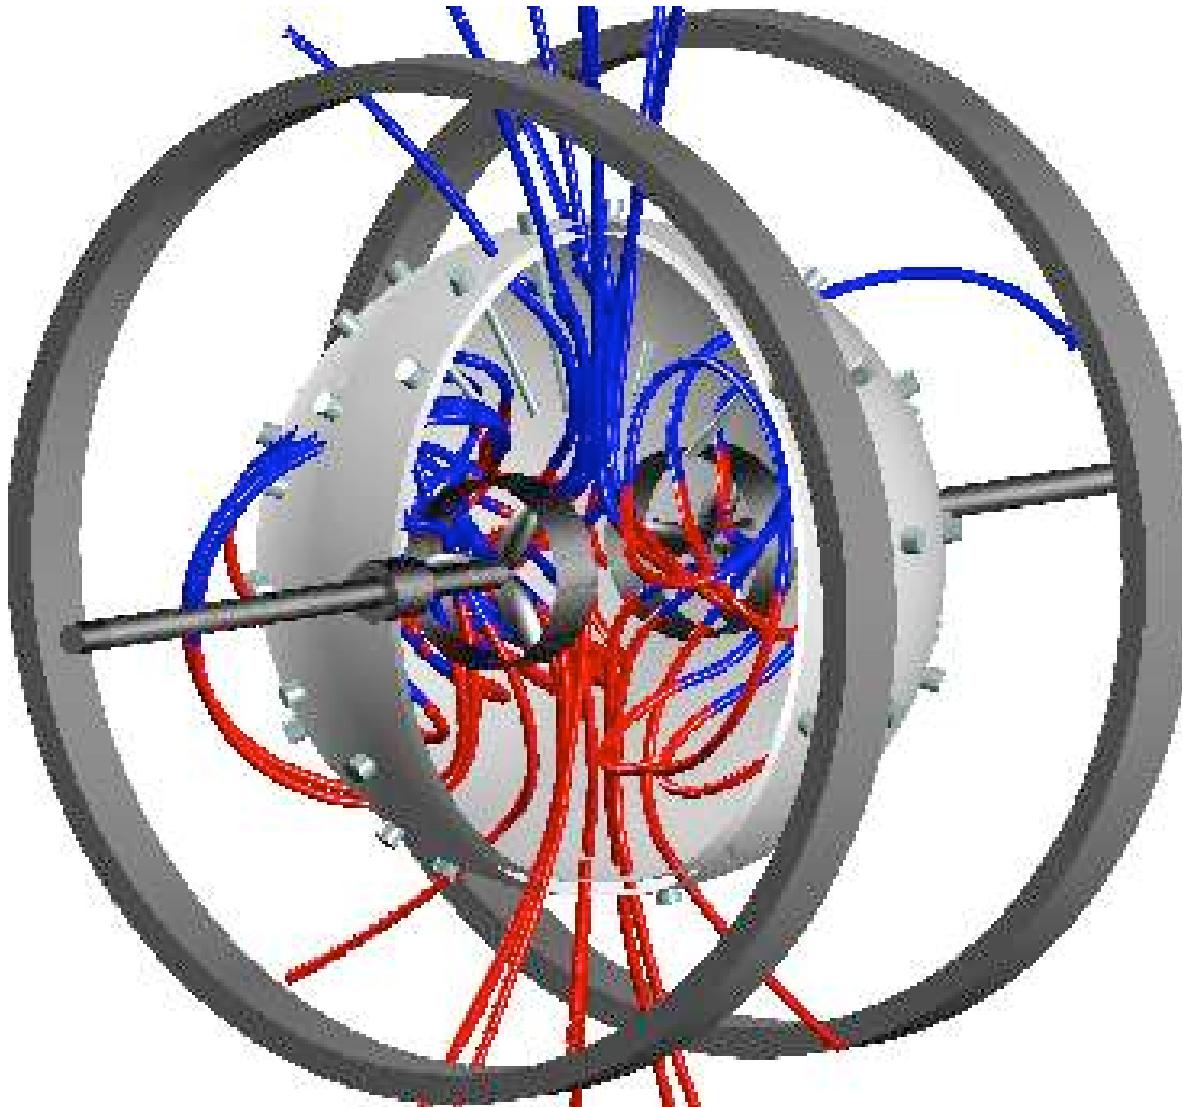

Velocity measurements have gaussian PDFs and Kolmogorov spectra

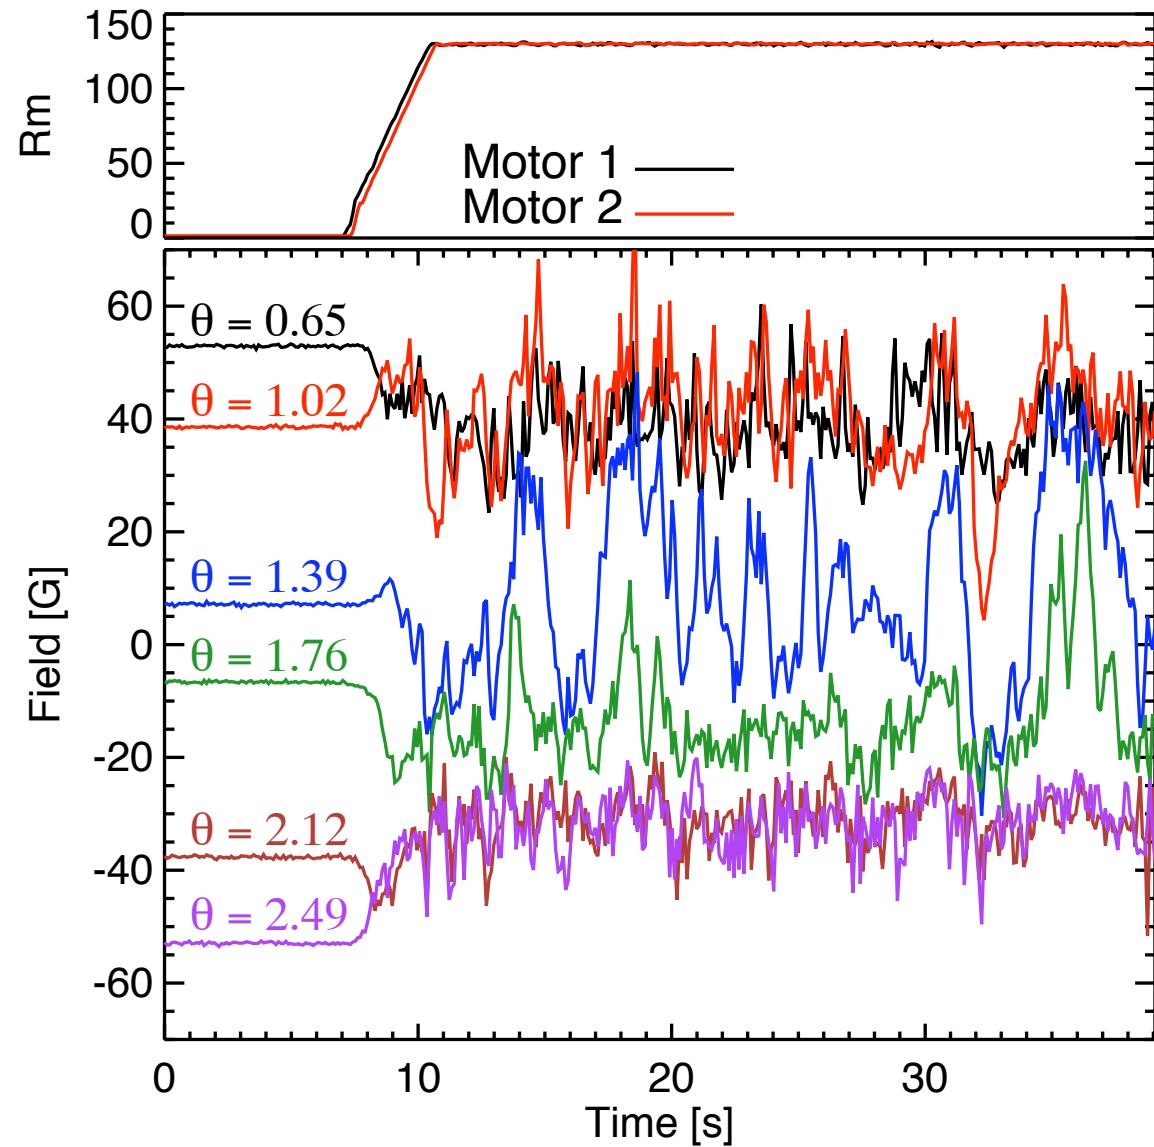

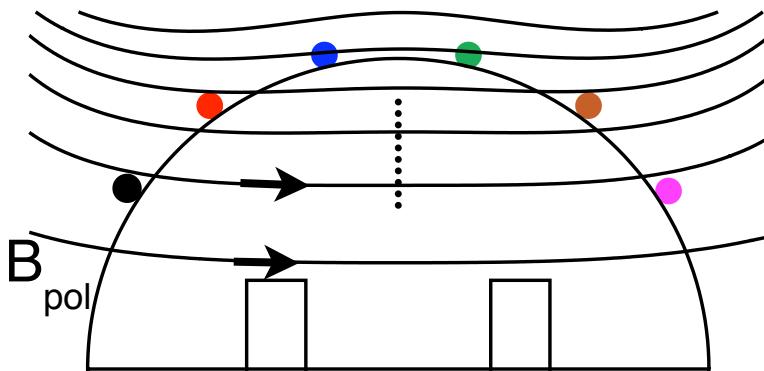

Changes in the large-scale flow profile can change the dynamo threshold

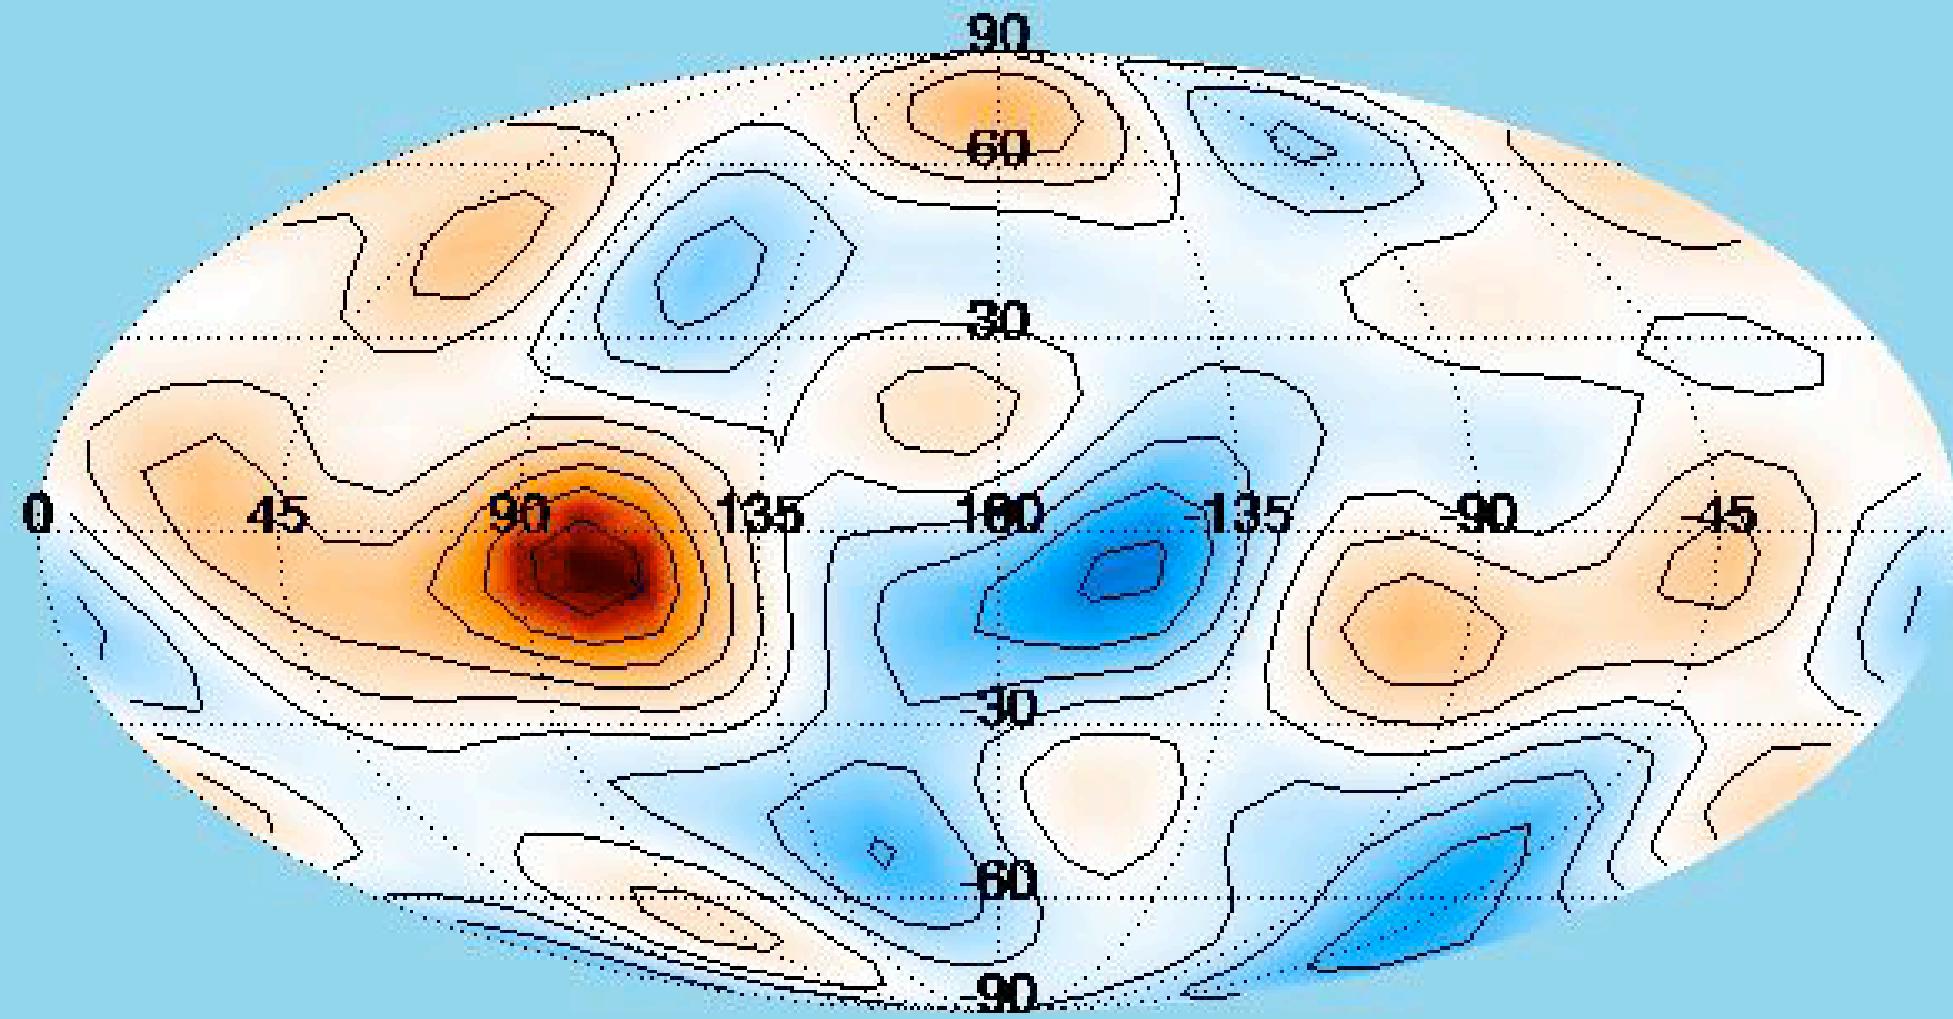

Laminar model predicts excitation of transverse dipole field

Magnetic fields are induced by the turbulent flows

Time: 0.02 s

Response Field [G]

Magnetic bursts have same structure as laminar dynamo prediction

Conditional averaging is used to determine growth rate

Energy Probability Distribution Functions become Poisson at higher rotation rates

Summary

- Turbulence can change threshold for field growth leading to intermittent excitation
- Observed intermittent bursts of magnetic fields with the structure predicted from a laminar dynamo model
- Field bursts gain strength and frequency with increasing impeller rotation rate
- Duration of bursts shortens so that they remain rare events
- Intermittent growth is possible even for flows which are on average sub-critical
